Building an Automated Behavioral Malware Analysis Environment using Open Source Software

The first question one might ask is why build our own analysis environment when there are a growing number of services (free and otherwise) such as the Norman Sandbox, CWSandbox, Anubis, ThreatExpert, etc. that will do the analysis for us. The primary answer is that, for privacy and policy reasons, there are some samples of malware that we encounter on a regular basis that we simply are not at liberty to share with other entities or organizations with which we do not have privacy or non-disclosure agreements.

1. Abstract

This paper describes how an automated behavioral malware analysis environment for analyzing malware targeted at Microsoft Windows can be built using free and open source software. The environment described here is an evolving work-in-progress, but what is in place to date is the culmination of lessons learned over the last two years of development by the author. This work was done as part of the author's employment with the AT&T Chief Security Office. While the author uses the royal "we" in places throughout the paper, the work is that of the author except where noted.

2. Motivation

The first question one might ask is why build our own analysis environment when there are a growing number of services (free and otherwise) such as the Norman Sandbox, CWSandbox, Anubis, ThreatExpert, etc. that will do the analysis for us. The primary answer is that, for privacy and policy reasons, there are some samples of malware that we encounter on a regular basis that we simply are not at liberty to share with other entities or organizations with which we do not have privacy or non-disclosure agreements. This is a point that probably deserves more emphasis. Samples may be gathered from any number of sources ranging from honeypots to specific network monitoring to internal investigations or from other trusted sources, and in most of those cases, without careful examination of the sample, it is not clear in advance that there is not data in the sample that might be sensitive. Policy therefore, is that, until proven otherwise, the samples must be treated as if they might contain personally identifiable information.

Jim Clausing

3

One might further ask, well, then Norman, the CWSandbox, and some of the others also come in commercial versions that one could purchase, why not just use them? These and other commercial products have been examined, and in some cases purchased, but we have also noted that these commercial tools sometimes give differing results for the same sample and different results from what our environment produces, for any number of reasons (including, but not limited to issues with virtualization or detection of the sandbox). So, even with these products, we will continue to develop and enhance the environment described here.

3. Purpose

There are clearly weaknesses and limitations to the environment described herein, some of which may be addressed in the future and some by design or on which we choose not to spend time. The company is not an anti-virus or anti-malware company though security services are among those offered. The goal of this environment is not necessarily a complete understanding of absolutely everything that the malware does. Since the company's business is providing network services, the resources available for malware analysis are necessarily limited. The first purpose of this environment is the quick preliminary analysis of the malware sample to determine whether additional manual analysis is required or desired. The second purpose is to provide input into a security data system from which we can, for example, attempt to track bots, botnets, or network attacks in order to mitigate them and/or alert our customers.

This project was begun essentially without a budget, hence the reliance on free and open-source tools. This also means that it can be relatively easily be duplicated and adapted by others who can

benefit from the lessons the author has learned to this point. The only money required to duplicate our environment would be for 2 PCs (one could use some surplus older desktop machines that were recently upgraded) and a legal copy of Windows 2000 or Windows XP. We started the project using Windows 2000. We later added the capability to choose between Windows 2000 or Windows XP SP2 (no SP3 yet, though it wouldn't be hard to add) as the client under which to run the sample, though to be honest, we rarely use the Windows 2000 image anymore since there are fewer and fewer of those systems installed. Windows Vista presents a few additional challenges (mostly requiring newer hardware) which we have not yet addressed since we have yet to deal with a sample that specifically targets Vista. We shall cross that bridge when we come to it.

4. Setup

The environment is built around Joe Stewart's TRUMAN sandnet. As Joe explains (Stewart, 2005)(Stewart, 2006), the idea behind a sandnet is that we allow the malicious software to execute in a controlled environment where it cannot harm any other systems. This is done by emulating the internet, not allowing connections to the real thing. This too has its downside, since we cannot see what the sample might do after it connects to its command and control (C&C) channel or what might be contained in any additional software it may download via HTTP, FTP, or some other protocol. Understanding these limitations, we still feel that TRUMAN provides an excellent basic framework for our automated behavioral analysis. Unfortunately, Joe has stopped developing the environment, so we shall distribute our modifications and bug fixes ourselves as patches on the author's website (http://handlers.sans.org/jclausing/grem_gold). The TRUMAN

Building an Automated Behavioral Analysis Environment

environment consists of a Linux server (flavor is unimportant, though we use Redhat Enterprise Linux 4 (RHEL4) since that was the corporate standard distribution when the project began, but pretty much any Linux distribution will work here) and the client machine which will at various times run Linux or Windows. David Bianco (Bianco, 2008) has put together some excellent notes on the NSMWiki on setting TRUMAN up for the first time, so we will not repeat any of that here. Our setup differs some from what David describes, for example, we use a client with 512MB of memory so that even with the memory dumps the entire disk image is 2GB. We are using fast ethernet (100MB/sec) NICs in both machines because they were too old to handle 1GB/sec NICs. We also have a much larger RAID array on the server so that we can store the images and analysis from quite a few samples. We use the userland NTFS-3g drivers (Wieers, 2008) to handle mounting NTFS file systems on the Linux server (see the explanation in the disk image analysis section below) and we have chosen to stick with the 4.5.6.x network scheme that Joe describes. The network between the client and the server can be through a real switch or simply a crossover ethernet cable. As stated earlier, we have the ability to choose between Windows 2000 or Windows XP, this is done by changing a softlink to the image that the server returns to the client. The Windows images themselves are basically vanilla Windows installs with just a couple of additional tools and scripts installed. Beyond what David describes in the Wiki, we have added *fport* from Foundstone (now part of McAfee) and dump the output of it and *netstat* to text files that become part of the disk image returned to the server. We have also installed a VNC server (we chose RealVNC, though a free one could be used just as easily) for those instances where some sort of interaction (such as clicking on a button in a dialog box) is required before the malware does anything malicious.

Jim Clausing

6

When Joe originally released TRUMAN, he provided a few scripts to emulate internet services, *pmodump.pl* - a Perl script to reconstruct the virtual memory space of a running process from a physical memory dump, *dumphive* - a program to dump the Windows registry hives, and he captured the network traffic to a pcap file. That was about it. The analyst was left on her/his own to figure out what was going on beyond running the Unix/Linux *strings* command on it and hunting through the registry dump. That quickly proved inadequate for our purposes, so the environment continued to evolve. As a need to extract additional data emerges, we determine where the data might be located and then we find and/or write tools/scripts to extract it. The pieces that we have written or modified to date are all available at the author's website (URL given above).

5. Analysis

As the title of the paper suggests, we are interested in behavioral analysis of the malware we are examining. The question then, is what behavior and how do we analyze it? There are 4 major areas that we concern ourselves with in this analysis: a) network traffic; b) the disk image; c) the memory image; and d) static analysis of the binary. Appendix B shows the analysis flow at a high level.

a) Network traffic

The network traffic is captured while the sample is being run and saved to a pcap file (well, the first 10,000 packets, we do not really need to capture all of the scanning of some of the noisier samples, like the recent Conficker.A). After the sample is run, the pcap is analyzed using a number of tools. First, we generate a brief

report showing source and destination IP addresses and ports, the amount of data (in bytes and packets) transferred between the two, and the start and end time of the communication. This is done with *ipaudit* (Rifkin, et al, 2005) (an example of the output from all these tools is in the sample report in Appendix A). The pcap is further analyzed to determine what other protocols are in use by running *tshark* (the command-line version of Wireshark (Coombs, 2008)) against it to get the protocol summary, then *tcptrace* (Ostermann, 2003) is run against it to pull out any HTTP traffic on port 80. As mentioned earlier, TRUMAN comes with several scripts to emulate network services. We have instrumented and extended these scripts to have them generate log files that we include in the reports (again, the logs are shown in the report in Appendix A, the modified scripts are available from the author's website). These scripts implement fake DNS, SMTP, SMB, and IRC servers. We also take advantage of the Apache server we have on the server that uploads the malware and disk images to the client. In particular, we have installed a self-signed SSL certificate and use the Apache logs to see what HTTPS URLs the malware may be attempting to download. We then take advantage of the redirection capabilities of *iptables* (standard on most Linux distributions) on the server, to redirect traffic to most other TCP ports back to the IRC server since most of the malware that we have examined to date use IRC for command and control and the script that emulates IRC records all of the data that it receives in its log file. This does leave us with some problems when the malware uses some sort of peer-to-peer communication for command and control and that is an area we continue to investigate for better solutions. At the moment, this data ends up in the pcap file and in the IRC log which has worked for us, but there must be better solutions.

One of the results of this analysis phase is information on DNS names and/or IP addresses that may need to be investigated for the presence of either a botnet controller or additional malware. In some cases, it may also provide data on how the malware propagates and may suggest mitigation or detection steps that could be taken within the network.

b) Disk image

One of the behaviors that we are interested in is whether or not the malware creates or modifies any files on the disk. As part of the TRUMAN run process, the malware is placed in `C:\Windows\system32\sandnet.exe` on the client, so we run *AIDE* (Lehti, et al, 2006) against the disk image after the malware is run and compare it to the clean image that was uploaded to the client before the run and take note of files added, modified, or deleted during the malware run. We mentioned earlier that we run the NTFS-3g drivers. These are not the standard NTFS drivers on RHEL4 (though they are on some newer distributions), but some time back we began to worry that with the stock drivers we might not be able to detect changes the malware might make to NTFS Alternate Data Streams (ADS). After some research, we determined that the ADS were detectable under Linux if we ran the NTFS-3g drivers, so we made the switch. While the latest version of *AIDE* should be able to look for changes to extended attributes (which is how the NTFS-3g represents ADS), we additionally run *getfatattr* against the image to look for the presence of ADS.

Another area of the disk image that we investigate is the Windows registry. For this effort, we use 3 different tools, 2 sets of Perl scripts and one binary. The first tool we tried for this (and we still keep this version of the output, but frankly don't look

at it too much anymore) is *dumphive* (version 07-31-2004-fpc) included with the TRUMAN distribution. We ran this against the pristine image and we run it against the image after the malware has been run and compare using the Linux *diff -u* command. The biggest problem with this (and the next tool we tried) is that many registry values and timestamps change in the normal course of operation, so trying to determine which changes/additions/deletions were malicious was difficult, and frankly we know that some went unnoticed. The next tool we tried was *regdiff.pl* by James McFarland (McFarland, 2008). As with the previous tool, the problem was in attempting to determine which changes were malicious and which were just part of the normal course of operation. When we started using this tool it was version 0.30. The most recent versions of the package contain a couple of additional scripts that we should probably take a look at, such as *regtimeline.pl*. Most recently, we have been using Harlan Carvey's *regripper* (Carvey, 2008) software to concentrate on any changes to Run/RunOnce keys or Services (though this software has the ability to do much more than we are doing with it). These are the primary methods by which the malware might attempt to ensure that it runs again after the system has been rebooted. One of the problems with *regripper* is that it is primarily intended to run as a GUI application under Windows itself, though we have recently become aware of several methods for running the GUI on Linux. Since we wish to do our analysis in an automated and scripted fashion under Linux, we again made a few changes to the software. In particular, Harlan expects that the memory image, script, and the plugins subdirectory will all be in the same directory. We modified the command-line script *rip.pl* to fix a minor bug and allow us to specify on the command-line where the plugins directory is located. We have submitted the patches back to Harlan, but he has, to this point,

Jim Clausing

10

chosen not to include them in the current version of *regripper*. Our patch can be found on the author's website. We also used a couple of Harlan's plugins as the basis for creating a couple of our own (and we changed the output to a pipe delimited format that worked better for our purposes). These, too, are available from the author's website. From this phase of analysis, we gather a great deal of data that can be useful for investigators who examine (potentially) infected systems.

c) Memory image

As noted earlier, one of the scripts that Joe Stewart includes with the TRUMAN package is *pmodump.pl*, a Perl script that searches through a memory dump for a particular process, then extracts the executable from the process' virtual memory. When Microsoft released Windows XP SP2, they introduced PEB randomization which changed the location of some of the process data structures in the memory dump (Whitehouse, 2007). When we added the Windows XP SP2 image to our environment, the original *pmodump.pl* was unable to locate some of the processes in memory in order to extract the executable. We have patched *pmodump.pl* to handle this PEB randomization and sent the patch back to Joe Stewart, but as he is no longer working on TRUMAN, he has not released an updated version of *pmodump.pl*. This patch can be found on the author's website. Once the executable is extracted, we run the Linux *strings* command on it and look for "interesting" ones. In particular, we look for IP addresses and DNS names of possible command and control servers. We also look for evidence that the malware attempts to subvert antivirus software by either shutting it down or adding entries to the hosts file to redirect update attempts to 127.0.0.1 (localhost).

One of the huge advantages of an environment that allows the malware to run on an actual machine, is that we can get the software to unpack itself, so that we do not need to necessarily identify (though we try, see static analysis section below) and find an unpacker for the particular packing/obfuscation used on the sample. We also use Jesse Kornblum's *ssdeep* (Kornblum, 2009) to do a fuzzy hash of the unpacked version to use for correlating samples to determine which samples might be related to which other samples.

For additional memory analysis, we rely primarily on the outstanding work of Aaron Walters and friends on the Volatility framework (Walters, 2008) and anxiously await the new features and capabilities coming in version 2.0. We actually use the *vaddump* and *procdump* plugins to dump the virtual memory of running processes the same way as *pmodump.pl* does, and we do the same strings analysis of those dumps. We further, use the *pplist* and *psscans2* plugins and compare their output to each other and to the builtin *netstat* command to see if any of the running processes are attempting to hide themselves via some sort of rootkit. Similarly, we use the output from *fport* and the *connections* (and *sockets*) plugin(s) and compare them against the results of the *connscan2* and *sockscan2* plugins again looking for processes that are attempting to hide themselves from the system. The *connections* and *connscan2* plugins should show us established network connections, while the *sockets* and *sockscan2* plugins show ports on which the malware may be listening for incoming network connections. We encounter numerous malware samples that inject DLLs into the Windows Explorer process or get loaded as a running service via *svchost.exe*, but dumping those entire processes leaves us wading through a great deal of extraneous data, so we continue to investigate other methods of analyzing these samples (see

conclusions and future work section).

d) Static Analysis of the binary

The static analysis performed on the malicious software is fairly limited at this time. We begin by running the Linux *file* program against it which usually just tells us that the malware is a Windows binary, but sometimes it also tells us about packers. We run the binary through anti-virus software (currently using the corporate standard A/V software and ClamAV (Sourcefire, 2009) since it is free), with signatures updated nightly. We take multiple hashes of the binary, the industry standards, MD5 and SHA1, plus *ssdeep* as described earlier for correlation purposes. We also run the Linux *objdump* against the binary. This may show us some of the structure of the binary, what the various sections of the binary are, etc. We also run Chris Rohlf's *binhash* tool (Rohlf, 2007) which generates MD5 hashes of the headers and data in each of the sections of the PE file. The original intent was to use this data for correlation purposes, but we have gotten sidetracked from that effort, so at the moment, this data just sits in the report. We hope to return in the coming months to this avenue of investigation and see if this is a useful tactic for correlating related malware. We then use the author's *packerid.py* script (Clausing, 2007) to attempt to identify any packer that may have been used on the binary (this script utilizes Ero Carrera's *pefile* library (Carrera, 2008) and as such is capable of producing more data than we actually use it for at the moment). We further run *strings* against the original binary. If packers are involved, this last step does not usually yield us much of anything useful.

e) Pulling it all together

The entire analysis process is run from the *submit.sh* script (found on the author's website) which oversees the entire process. It takes as an argument, the name of a binary or a ZIP file. If the latter, it unzips the file. Then it copies the binary to the directory from which it will be uploaded to the client, starts up the fauxservers and then starts up *ngrep* and *tcpdump* which are displayed on the tty so that the analyst can monitor the network traffic as the sample runs. This is useful, in that it allows us to recognize when the sample is attempting to communicate on a port that is not being redirected or when it is not communicating at all which may be an indication that there is a dialog box on the client that requires a click before the malware can continue execution (in which case we can fire up VNC). When the 10 minute run on the client terminates and the disk image has been transferred back to the server, the *submit.sh* script, executes the *forensics.sh* script (also available on the author's website) which runs all the aforementioned tools on the disk, memory, and binary described in the preceding section. Finally, the *submit.sh* script runs the *summary.sh* script (also available on the author's website) which pulls the results of all the tools into a text report which summarizes the results of the analysis (see the example in Appendix A).

6. Conclusions, Future and Related Work

As stated at the beginning of this paper, the environment described here is very much a work-in-progress (as evidenced by the fact that this paper has taken 4 months to write because we continually went back and fixed/tweaked the environment as we were writing). We have noted limitations at various points as we have

discussed the environment and we will undoubtedly address some of them. The environment as it currently exists can process one sample every 20-25 minutes which includes 10 minutes of actual execution time on the client. The primary factor limiting throughput at the moment is the network hardware, since the automated analysis completes before the pristine image has been downloaded back to the client. We mentioned earlier that we had installed a VNC server on the client. Early on we discovered that some samples did not seem to do anything during the 10 minutes that they ran or in very rare cases, the execution did not terminate after 10 minutes. With the addition of the VNC server, we can, when necessary, connect to the client and click on dialog boxes. This means, however, that we have not achieved the ability for entirely hands-off analysis. There are some tools that we may consider adding in the future to overcome this limitation.

We have found the fauxserver scripts to be adequate in simulating the internet for most of our samples, but Tyler Hudak (Hudak, 2009) recently noted in his blog that he is using InetSim (INetSim, 2008), so we may take a look at that to see if it provides us any additional capabilities.

One area that we continue to work on is the memory analysis. We are beginning to look at Brendan Dolan-Gavitt's registry plugins (Dolan-Gavitt, 2009) to Volatility to see if the in-memory version of the Windows registry has been modified but not yet written back to disk. We also are looking at Michael Hale Ligh's *malfind.py* (Ligh, 2009) for finding malicious DLLs injected into other running processes.

One of the other huge limitations of this environment is that the analysis is all done after the execution of the malware. The

environment is not instrumented to collect information on system and library calls as the malware executes. The recently announced Zerowine project (Koret, 2009), however, appears very intriguing as it does exactly that, so we may look into augmenting the current environment by also running the sample through zerowine at some point in the future.

7. Acknowledgements

This work would not have been possible without the support of our management, Cynthia Cama, Bill O'Hern, and Ed Amoroso, and the assistance and suggestions of the rest of the team. In particular, we'd like to thank John Hogoboom, Dave Gross, and Brian Rexroad for their thoughts and allowing the author to bounce ideas off them.
