Abstract

Responding to incidents in an efficient manner is critical for all CIRTS. This paper presents a new open source tool for the enterprise. With this tool, responders will be able to detect incidents using aggregated data collected from hosts and applying anomaly detection. OHIDS includes a sensitive data finder to allow appropriate escalation of the incident. This software can be utilized in a proactive manner by removing SSNs and credit card data before incidents occur or by detecting unauthorized software running.
1. Overview

Detecting and analyzing intrusion based solely on network traffic gives you an incomplete picture, especially if you are lacking full packet captures or if you have a large number of mobile users who do not always use your Internet connection. This is a common struggle with most Computer Incident Response Teams (CIRTs) and they need a fast way to determine if the system is compromised no matter the location. A host based IDS (HIDS) for Windows that feeds into a central database and uses the power of base lining and comparison can meet these needs. OHIDS collects running processes and other key detection mechanisms, along with a sensitive data scanner. By using this HIDS in conjunction with network based alerting, it should allow CIRTs to assess if not only the attack was successful, but also the impact based on what data is on the system.

According to Caswell, Beale and Baker (2007), Snort introduction to the world was on December 22, 1988 (Chapter 2, what is Snort). Network IDS can detect many different malicious activities including exploits, port scans, non-compliant protocols and brute force attacks. Network IDS is also a great way to detect malware infection because most malware needs a way to communicate back to the attacker. This method of analysis is called extrusion detection (Bejtlich, 2006, p. 4).

One of the main drawbacks of traditional network analysis is that malware can easily encrypt, obfuscate or purposefully mangle its communication over the network. In a recent GCIA Gold, “Beating the IPS”, Michael Dyrmose (2013) discusses how easy it is to bypass IPS technologies (p. 59). To combat just encrypted traffic, you will need to force all traffic to be decrypt before it enters or exits your network. In many environments, this is not possible due to privacy concerns, which enables malware to sneak past with ease.

How do you detect malware when we do not have a signature? How do you detect a laptop compromised at home? Base lining the network and hosts is the best defense against this, but is a difficult thing to accomplish in large distributed environment.

What we are missing is determining the impact of the infection on the system. Depending on your environment, you may be able to segment departments into different subnets. This would give you some indication that a system in the human resource
department, but you still do not know if the individual's computer has personally identifiable information (PII) or how much of it.

To fill this gap an open source HIDS will help determine anomalous activity on the system. Some of the more common features in HIDS include log monitoring, process monitoring and network traffic analysis. These features can be used to help detect basic malware, intelligent advisories or even configuration management. Once detected from the network, the information gathered from forensics analysis can be used to query OHIDS to find additional infections.

According to Innella (2001), Haystack Labs released a product name Stalker in 1989 (A Brief History, para. 5). This appears to be the first commercial version of a HIDS. A presentation from Steve Smaha (1996), the president Haystack Labs, states the patent pending technology includes gather data from “Processing system audit trail records, system log file data, and system security state data” (slide 7). While OHIDS is collecting a lot more information, the basic ideas from the Stalker software still apply today.

OSSEC is a great open source project that does log analysis and can detect changes to the registry, file system changes and many other things. The main difference between OSSEC and OHIDS is that you cannot easily use OSSEC as an incident response tool to collect live data from a large number of hosts.

2. Introduction to OHIDS
The first version of OHIDS started in 2007 and it was a batch script to collect basic information. An intern, Maryam Jafari in 2009, wrote the second generation in VB script. This version added a few additional items to collect and the output was dumped to a network share. Another intern, Vipul Gupta in 2010, ported the third version to VB.net. Additional functionality of hashing of processes and loaded modules was added. In the fourth version, output was converted to CSV and imported into a database. This, the fifth version, has the capability to connect to the database making it the first true version where others can easily deploy it in their own environment.

Tom Webb, tcw3bb@gmail.com
2.1. **Architecture**

The OHIDS client is written in VB.net using the 4.0 framework. It will collect the following critical system stats: running processes, loaded DLLs, network connections, firewall rule set, services, startup items and scheduled tasks. Each of these stats can be used to determine what is currently running on the system and what functionality the application may have. These items will allow us to differentiate what is normal and what is abnormal for systems on the network.

Each system will connect back to a database server, currently on a daily interval, were the data will be processed and correlated. Additionally, every seven days, the OHIDS client will run a sensitive data scan, using a modified version of Find_SSN(Find_SSN, 2009), on pre-defined directories and insert the results into a table on the database server. Find_SSN is a python script compiled for windows, which scans for social security numbers and credit card numbers. The version packaged with the system is modified to reset the access times to any file that it reads. This prevents stomping on any potential forensics evidence in case a full investigation is required.

2.2. **Known Weaknesses**

The VB.net client collects data from the system using the Windows API calls and built-in windows utilities. While this technique is convenient and allows for fast development, malware can bypass this method of detection by hooking API calls, injecting DLL’s or using a rootkit to manipulate the data OHIDS is collecting. Lots of malware still does not use these techniques and OHIDS is able to find them.

To detect hooks, rootkits or injected DLLs you can use a malware scanner like Malwarebytes Anti-rootkit or GMER that looks at program anomalies. My preferred method for detecting this kind of malware is memory analysis using Mandiant’s Redline to detect anomalies by directly accessing windows memory.
2.3. Use Cases

2.3.1. Sensitive Data, Malware Type, and Incident Classification

In most enterprise environments, network IDS detects infections many times an hour. Each of these infections must be prioritized and categorized appropriately to use the incident responders’ efficiently.

According to Cichonski, Millar, Grance, and Scarfone (2012) your incident response policy should include your expected response time based on assets criticality and threat level of the malware (p. 32). If you are lucky enough to have an enterprise data loss prevention software deployed, then you should be leveraging this information to set response priority. If not, you will need to rely on the helpdesk or have your responder contact the user to determine what information they use on a daily basis. Based on my experience, this method has proven to be very unreliable. Users generally do not want to “Get into Trouble” if they use sensitive data and therefore downplay the data they access. Other users do not want to lose productivity time and have been less truthful. Some users have a hard time actually determining what sensitive data means, even after several discussions. With OHIDS, you have data pre-populated in a database to query. This can be a huge time saver and enable your organization to have consistent data to reference.

2.3.2. Detecting Unknown Malware

Malware is a difficult problem that IT professionals have been fighting for a long time, but after doing incident response for a while one thing seem to be the same. Most malware wants to have a persistence mechanism to insure the system is infected as long as possible. This seems to be one of the fastest and easiest ways of detecting most unknown malware, especially if you have a large list of data to compare. While this method will not catch rootkits or other techniques, it should work well for run-of-the-mill infections.

Finding unknown malware requires a basic understanding of malware and analytics to identify places where it is hiding. The following is a list of simple but powerful techniques that will be used for detecting malware.

1. Least occurrence analysis of registry settings, running processes, and loaded DLL’s when compared to all known PC in your infrastructure.

Tom Webb, tcw3bb@gmail.com
2. Look for common locations where malware hides

3. Compare daily system changes in the registry, running processes and services to help focus analysis.

Least occurrence analysis can be used to determine unique settings or process running on systems. With a large number of systems in the database, most systems will have the same applications running. Individual computers running a unique process stand out. Many version of malware still generate random file names, which can be detected quickly using this method. Additionally, by reducing the dataset, you can scrutinize these items more by searching for MD5 and other signs to detect malware.

Malware has a few common places that it likes to hide, and looking at these specific places can quickly detect infection. Some examples are anything running in temporary folders. According to Niemelä (2012), some of the common locations are C:\Users\USER\Documents\, C:\system volume information\, and c:\$Recycle.Bin\ (slide 22).

Once you have used the first two techniques for detecting malware, you should have confidence that you have found at least the obvious infections on your systems. Now we can compare the “known good” configuration of these systems each day and determine what is new. This will greatly reduce the amount of data that needs analysis. It is still good to re-establish a baseline on a monthly basis to make sure nothing has slipped through.

2.3.3. Using Indicators of Compromise

When performing malware analysis on new sample you should catalog changes made to the system by the infection. Once there is a good understanding of the malware, you can generate an indicator(s) of compromise (Frazier, 2010). Indicators can be as simple as a file name or just a hash of a file. Other indicators may include file paths, process mutexes, or a service ran as a different user. To track these items and make them easily shareable, Mandiant has create an open XML framework called openIOC (http://openioc.org). They have a GUI tool that makes it easy to use the predefined

Tom Webb, tcw3bb@gmail.com
schema for creating new entries. This allows for consistent sharing of data to different groups.

Once these items have been found, they can be queried against the database indicating other infected systems. By leveraging OHIDS, you may find systems that are lying. By definition, network IDS fails to detect anything that does not send traffic over the network.

3. Client coding designs

3.1. Client Configuration

There are several things to configure on the client before you can get started. To make these changes, you will need to edit the app.conf file in the directory where the main executable is located. The following items can be changed for your deployment: Database IP, Database Name, Database UserID, PASSWD, Registry Path to store basic information and path for the temp directory. This is covered in more detail in section 4.0

3.2. Main Function

The main function of the program has only a couple of checks and then calls the critical sub functions Analysis. Figure 1 is a map of the main function of the program.
3.3. **Input**

This section will cover collecting data from the PC. The client is not allowed to read any table in the MySQL database directly (e.g. the user has limited rights to only insert) and must use stored procedures for any queries. Additionally, they can only insert into temporary tables and not in the permanent tables.

3.3.1. **Analysis Function**

This function collects the majority of the data for the application. The PC_Id is the unique number that is stored in the PC_Info table for each computer as the primary key. Before we can start generating results from the data, we need to know the PC_Id for this system. To do this, we call the function comid_sql that uses a stored procedure (Appendix B) to query the table and determine if an entry for the computer name already exists, if so, it will respond with the corresponding ID. If no name exists in the table, it creates a new ID and placeholder information. Once the client has determined its PC_Id, it will then proceed to collect data. Figure 2 shows how the analysis function flows.

To make sure OHIDS does not greatly effect performance, a sensitive data scan runs on a weekly basis and is set to a low priority. The last date Find_SSN.exe is run gets stored in the registry key defined in the app.config file in HKLM hive.
Figure 2. Analysis function flow in OHIDS client.
3.3.2. Netstat

To get a list of programs that have current connections and listening ports open, we use the netstat –nao command. The output redirects to a temporary file and parsed using the NetstatInform function.

3.3.3. Process list, MD5 and MAC Times

The ProcInform function collects information about the process running on the system. Additionally, it collects information on the modules loaded including MD5, PID, Parent PID and MACtimes for each process and module.

To gather a list of processes, the windows API System.Diagnostics.Process.GetProcesses() is used. WMI is used to get the parent process id (PPID) and modules for each process and results are written to a file. MAC times will be gathered for each file, using windows API, along with MD5 and File version information. Figure 3 gives a breakdown of how the function collects data.

Figure 3. ProcInform function application flow in OHIDS client.

Tom Webb, tcw3bb@gmail.com
3.3.4. Schedule Tasks

The list of scheduled tasks are generated via the built-in utility scDisk /query /v /fo csv. The output lists items any item scheduled with task scheduler or the command line at.exe. The csv file is parsed and loads into the database.

3.3.5. Services

Service information is gathered using ServiceController.GetServices vb.net call. This information writes to a file, parses and loads into the database.

3.3.6. Startup List

Startup information is gathered using the WMI call Select * from Win32_StartupCommand for StartupCommand. This list includes many different items that start when the system boots or the current user logs into the system. The results are placed directly into the table using a SQL insert statement eliminating the need for a temporary file written to the host.

3.3.7. Firewall

The windows firewall rules are collected using the built-in command netsh firewall show allowed program. According to Microsoft, the policy description standard means these rules are applied when the computer is not connected to the same network as the domain. The domain description means these are applied when the system is on the same network as the domain (Microsoft, 2005). This output is redirected to a file and based on the on which OS the file is broken up into the proper format to be loaded into the database.

3.3.8. Sensitive Data Scan

OHIDS calls the sensitive data scanner find_ssn.exe two times, once for scanning the My Documents folder and the other to scan the current users’ desktop, and create two separate logs. The entire user directory is not scanned due to the large number of false positives when looking at the user’s temporary Internet cache and other file types stored in the folder.

Tom Webb, tcw3bb@gmail.com
3.3.9. **Error Log**

Error logging is straightforward. If the system cannot connect to the database, then an event log is created in the application event log with the source of OHIDS and event ID 234. If the database can be reached, all other logs are input into the Error_Log table for troubleshooting.

3.4. **Output**

All functions that have output use a function with the same name and ends in sql. These functions sends the output to the database and one example of this is the netstat_sql function.

4. **Database**

The database should be running on MySQL 5.1 or greater on a Linux server with at least 4GB of RAM. Storage should be approximately 1GB per every 2000 PC put into the system.

4.1. **Main Tables**

The main table, PC_Info, is where each computer in the database must have an entry. This table contains the PC name, IP, OS version, first and last time checked in and other overall information on the system. The primary key is the PC_Id that uniquely identifies each computer that communicates to the system.

To update data in the PC_Info table, a stored procedure compares the PC_Name with the PC_Id and hashes it. This is the only table that never has any data purged from it and additional checking helps with integrity.

The Process table includes information about each process and modules loaded. The Netstat table contains results from the netstat command. Service, Startup_List, Schd_Tasks tables all contain information to detect persistence in malware. The PC_Hash table contains a list of all process and DLLs running and hashes. The Error_Log table contains errors generated by the agents when running on the systems to help with troubleshooting.

Tom Webb, tcw3bb@gmail.com
4.2. Additional Tables

Several additional tables exist for whitelisting information; this will reduce the noise in the reports. The Good_Serv table is a list of default services installed on Windows XP and Windows 7 that was created. The Good_Hash table can be loaded with external lists of hashes or you can generate your own based on the company image. Using this table is covered in more detail in section 5.1.3. The Good_File table is used to weed out other items that you have investigated and want to remove from future reports. Items in this table must contain the full path of the executable. (e.g. insert into Good_File (Name) Value ('C:/Program Files/Trend Micro/OfficeScan Client/TmProxy.exe');) Currently, due to speed, wildcards are not supported for filtering. This makes it impossible to filter out applications installed in the user folder. To get around this, you can use the grep –v option on your output if needed.

4.3. Temp Tables

All major tables, except PC_Info, have a temporary version of the tables. This is a loading stage for comparisons, and is used to compare previous results to each other. A cron is setup to move the data daily from the temp table to the main table for storage.

4.4. Permissions needed

The SQL user for the client should have very little permissions. It should only be given insert permission to the temp tables and the ability to execute the two stored procedures used for the PC_Info table. This limits the client the ability to read any information from the tables except for what the stored procedures allow.

4.5. Stored Procedures

OHIDS has two stored procedures, get_com_id and update_comp_info. The specific code for each procedure is in Appendix B and Appendix C.

4.6. Daily Tasks

The ohids-daily-rotate script should have a link placed in the /etc/cron.daily. Before data is moved, the script purges all data in the long-term tables that is older than 45 days. The information in the PC_Info table is never removed. This script dumps the data, in CSV format, from the temp tables to the specified directory in the

Tom Webb, tcw3bb@gmail.com
DATA_DUMP_DIR variable. This data is for historical reasons to help with incident response when a compromise is not detected for long period.

5. Deployment

5.1. Client

You may deploy the application to a folder on a network share or to a local directory. The application and dependencies will all be in one flat folder directory. Copy this directory to the place where you want it to run from. To change the default settings for the temporary file location, registry settings, and database username use the XML file in the same folder. A scheduled task should be setup via GPO and have it run daily as the System user to run the ohids.exe file.

OHIDS creates application events logs with the event id of 234 if it cannot establish a connection to the MySQL database. If you are experiencing any addition errors, you will need to check the Error_log table in the database.

5.2. Requirements and options

For most external commands run via command prompt, the results create temporary files in the specified folder on the system. The following windows utilities are used to collect data: netstat.exe, netsh.exe, scrtasks.exe. Server Install

To get started, you will need a Linux system that is running MySQL. The ohids-install script is a simple script that will create the MySQL database, load the schema for the database and move scripts into the directory /usr/local/ohids. You will need to create a .my.conf in the home directory for the user you plan to run the script. You only need to include the username and password in the file for admin access to the OHIDS database. Make sure you set the permissions to 400 on this file. Edit the variables in ohids-daily-rotate.sh to make sure the script is working as intended.

Tom Webb, tcw3bb@gmail.com
6. Mining Data

6.1. Looking for signs of compromise

As previously mentioned in the use cases, we are going to use analysis of what has changed on the computers each day. We will also use analysis of unique process running in a large environment and using known hiding places to find malware.

6.1.1. Malicious process

When detecting a malicious process, you need to know what a normal place for processes to run from is. As mentioned previously, temporary directories and system volume info is commonly used by malware. To get a list of common reports use the OHIDS report script. Make sure the Linux user has a .my.conf file in the user directory with a username and password for the database. To run the report, use ohids-reporter.sh – proc_odd. This report (Figure 4) also looks up the process hash using Team Cymru hash lookup (http://www.team-cymru.org/Services/MHR/). The Cymru results shows the percentage of Anti-virus software that detected the hash as malicious. If the results contain NO_DATA, no AV has determined the software is malicious.

<table>
<thead>
<tr>
<th>PC_ID, Process Path, MD5, Cymru Results</th>
</tr>
</thead>
<tbody>
<tr>
<td>972 &quot;C:/WINDOWS/TEMP/DK9423.EXE&quot; &quot;cd6798a36930f0e224253c5db392d4f&quot; NO_DATA</td>
</tr>
</tbody>
</table>

Figure 4. Sample report from Proc_Odd.

To determine unique processes running in your environment the Proc_Uniq report (Figure 5) will help you find possible random malware named processes. The report lists process in your environment that has less than five computers running the process.

<table>
<thead>
<tr>
<th>Proc_Name</th>
<th>Proc_File</th>
<th>cat_num</th>
</tr>
</thead>
<tbody>
<tr>
<td>ODSAgent</td>
<td>C:/Program Files/DVD or CD Sharing/ODSAgent.exe</td>
<td>3</td>
</tr>
</tbody>
</table>

Figure 5. Sample report from Proc_Uniq.

One of the most powerful ways to query this data is to compare the previous day’s results to illuminate a lot of noise. The Proc_Diff report will show you only new processes running on each computer that were not running on the previous day.

Tom Webb, tcw3bb@gmail.com
Reviewing all the various Diff reports should be part of your daily security operations process.

<table>
<thead>
<tr>
<th>PC_Id</th>
<th>Proc_File</th>
</tr>
</thead>
<tbody>
<tr>
<td>83</td>
<td>C:/Program Files/Juniper Networks/Common Files/dsNcService.exe</td>
</tr>
<tr>
<td>83</td>
<td>C:/Windows/system32/svchost.exe</td>
</tr>
</tbody>
</table>

*Figure 6. Sample report from Proc_Diff.*

The Proc_Date report looks for processes that are running with a file create and/or modified date of less than 48 hours. This report differs from the Proc_Diff report as malware can use the same name as another process, but the malware may not have manipulated the file dates.

<table>
<thead>
<tr>
<th>PC_Id</th>
<th>File_Name</th>
<th>MD5</th>
</tr>
</thead>
<tbody>
<tr>
<td>1187</td>
<td>C:/WINDOWS/ASSEMBLY/NATIVEIMAGES_V2.0.50727_64/SYSTEM.MANAGEMENT/C54FC0CAC648A174C5E35BD6589C9390/SYSTEM.MANAGEMENT.NLDLL</td>
<td>0181b4c10f409299e0d8e130e07353</td>
</tr>
</tbody>
</table>

*Figure 7. Sample report from Proc_Date.*

If you want to dig deeper into possible malicious process with OHIDS, querying the process ID in the Process table will give you a list of all the DLLs. According to Sikorski and Honig (2012), you can use the loaded DLLs to determine some of the capabilities of the malware (p. 17).

**6.1.2. Detecting Persistence**

The Start_List table, Sch_Tasks and Service_List are the key tables when looking for items where the malware will reload when the system restarts. The Start_Loc report, queries the Start_List table, is the lowest volume and tends to have the highest accuracy for detecting infections. Like the process version of this report, the Start_Diff looks for typical places where malware likes to hide but only shows the difference between the same computers for the past 48 hours.

<table>
<thead>
<tr>
<th>PC_Id</th>
<th>Command</th>
</tr>
</thead>
<tbody>
<tr>
<td>15</td>

</tr>
</tbody>
</table>

*Figure 8. Sample report from Start_Loc.*

Tom Webb, tcw3bb@gmail.com
Figure 9. Sample report from Start_Diff.

6.1.3. Compare Software Hashes

Looking for software that is running the same reported version, but a different hash, can be tricky. You are relying on the developers to update the file version metadata any time a change is made. The Hash_Comp report (Figure 10) compares MD5 hashes of running exes and DLL’s with the same version number. If a hash does not match, it will display the name. I use this report as a final effort when other analysis is not working out. The success rate for detection has been very low on this report in my uses.

<table>
<thead>
<tr>
<th>Filename</th>
<th>Version</th>
<th>MD5</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADL.FOUNDATION.DLL 2.0.3299.28586 0a86b6caac2d01de4:56b15022a6b3b</td>

<td></td>
</tr>
<tr>
<td>ADL.FOUNDATION.DLL 2.0.3299.28586 1bbdbd33cd07ba45:493247a9b0be12</td>
<td></td>
<td></td>
</tr>
<tr>
<td>ADL.FOUNDATION.DLL 2.0.3299.28586 1d5a364193eed5a97803b95377ac15ee</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Figure 10. Sample report from Hash_Comp.

The most well known hash dataset is the National Institute of Standards and Technology’s National Software Reference Library (2009). You can also use their Knoppix CD to create your own list from your standard desktop image. By loading this information into the Good_Hash table, you can use it to reduce the noise in these reports. This can be done by comparing the results of the MD5s to the items listed in the Good_Hash table and only displaying items that do not match. If you want to have any your queries filter based on this table, you can add “WHERE MD5 not in (select DISTINCT MD5 from Good_Hash)” to the end of the query. This is already done in the Hash_Comp report.

If you are allowed to send data offsite or if you want to uses these hashes with other tools, the nsrllookup (nsrllookup, 2013) software allows you to send hashes to a database for lookups. The project is hosting a copy of the NSRL hashes to query for free, but if you use a third party, make sure you verify these results. By dumping the results of

Tom Webb, tcw3bb@gmail.com
the Hash_Comp report into a file and then running the following command “nsrllookup -s nsrl.kyr.us <hash” you get a list of only unknown hashes from the database.

6.2. Personally Identifiable Information Scan results

As mentioned previously in the use case 1.6.1, finding out which system has sensitive data is critical to determine what level of response you should provide to a compromised system. To get a list of sensitive data for a specific computer, use the –Ssn_Comp switch followed by the computer name (e.g. –Ssn_Comp ‘PC_ID’). The total includes the total number of SSNs and/or credit card numbers found on the system. The SSN_Top report include the top 25 highs totals.

<table>

<td>1.23.5</td>
</tr>
</tbody>
</table>

Figure 11. Sample report from SSN_Top.

This report will give you a list of files that contain possible social security numbers and/or credit card number count on the system. We do not keep track of the actual SSN/CCN found on the system. An additional indicator, if these are false positives, are location of the files and file names. For example, if you have a file that shows 5,000 PII count and it’s called mathematical_analysis_of_water_sample.xls chances are this is a false positive. The spreadsheet likely has many numbers in it for data samples. However, if the file name is Q3_finance_dept.xls it is likely to be a true positive and escalate this incident appropriately. You can also call the individual armed with this information and ask specific questions about these files. In this case, you will likely get an accurate response from the user.

7. Proactive Steps to prevent breaches

7.1. Remove Unnecessary Sensitive data

Incidents will continue to happen in every environment and the best protection from data loss is to remove unnecessary data completely from system. A very effective way to remediating this issue is generating a top 25-user report on a weekly basis (e.g. –SSN_Top). With this data, you can create a helpdesk ticket and have them contact the

Tom Webb, tcw3bb@gmail.com
user about the data in the specific report. In addition, you can have this report sent to management so they understand the higher risk areas. In many cases, the user had forgotten the data was there or did not need to keep it on their system. If they need to keep it, you should work to determine acceptable recommendation to mitigate risks.

7.2. Audit for unauthorized software

The Proc_Date report gives you a list of new software installed in the last 48 hours that was running on the system. This report can detect malware, but also detecting programs that are not allowed by policy (e.g., P2P applications, Cloud file sharing). If you have users running portable apps you will be able to detect this by looking at the path where the executable is running from.

8. Future plans

8.1. Gather Specific Event logs

Anyone who has looked at Windows event logs know they are very noisy. If you do not already have a centralized logging, then gathering a small number of events can be useful. Placing the event IDs you want to capture into the xml config will allow you to specify what logs you want to get back into the system. The NSA white paper “Spotting the Adversary with Windows Event Log Monitoring” contains a comprehensive listing of what event logs should be monitored (NSA, 2013). For Windows 7 systems, the following event ID’s will initially be the items of interest to collect: 4740, 4624, 4625, 865, 8003, 8004, 8006, and 8007.

8.2. On demand Scanning/Service

Having OHIDS run as a service would allow it to check-in at a short interval to the database and determine if it should run a new scan. This would then allow me to build a simple API to be used by an IDS to request data to be gathered on the host immediately. The data could then be quickly reviewed to determine if a network attack was successful.

8.3. API Hooking

Software like El Jefe (El Jefe, 2013), which hooks the create process API and records the information to a MySQL server, has been around for a couple of years. By

Tom Webb, tcw3bb@gmail.com
logging these specific calls, incident responders will know what processes are ran on a system and what started the process. Adding a similar functionality to this code would give CIRTs near real-time data on what is running in the environment. This is a much longer goal, as the on demand scanning will be easier to implement.

9. Conclusion

Network IDS will continue to be used for a long time, while integrating NIDS information into security information and event management (SIEM) systems has made correlation of successful attacks easier, but collecting key information from the hosts is still the most beneficial information for CIRTs. Using OHIDS in conjunction with NIDS makes it possible to detect an incident via the NIDS then gather detailed analysis and determine the amount of sensitive data stored on the system. With the hash of the malware, other online resources may have already performed an analysis of the executable. If so, you can quickly determine if the capabilities of the malware allows access to any sensitive data found on the system. All this can be completed before you start your forensics collection of evidence. With the provided data, you can determine if it is necessary to do any additional investigation or begin the clean up process. By eliminating the need for in-depth analysis in some incidents or speeding up the forensics process, OHIDS enables CIRTs to handle incidents more efficiently and enable them to spend resources on the more complicated cases.
